

Extended Bayesian Skyline Plot tutorial for BEAST 2

Joseph Heled
(updated for BEAST 2 by Tim Vaughan)

This short practical explains how to set up an Extended Bayesian Skyline Plot (EBSB) analysis in BEAST 2 [Bouckaert et al., 2014], and how to generate some EBSB plots.

To make the most of this tutorial you should follow the steps described here on your system. Reading the article [Heled and Drummond, 2008] first is not a bad idea either. Use your own data if you are comfortable with BEAST, otherwise use the provided examples. The next section uses the data in the ‘mystery-mammal’ directory, three genes from a small mammal: one nuclear, one mitochondrial, and one from the X chromosome.

This tutorial is based on BEAST version 2.3.2. Before proceeding any further, visit www.beast2.org and ensure you are running the latest version.

My sincere apologies for any harm done by the figures to your aesthetic sensibilities. Nobody, the Java team included, cares much for my preferred platform, Linux.

1 Setting up the analysis

1.1 Loading the data

The EBSB is a multi-locus method, so the step first involves loading all loci/genes into BEAUti. The simplest way to do so is to prepare one NEXUS file for each alignment. Taxa names in each alignment have to be unique, but duplicates across alignments are fine.

Start BEAUti, open the File menu and select ‘Import Alignment’. Navigate to the data directory, select all the files you wish included in the analysis and click ‘Open’ (Figure 1).

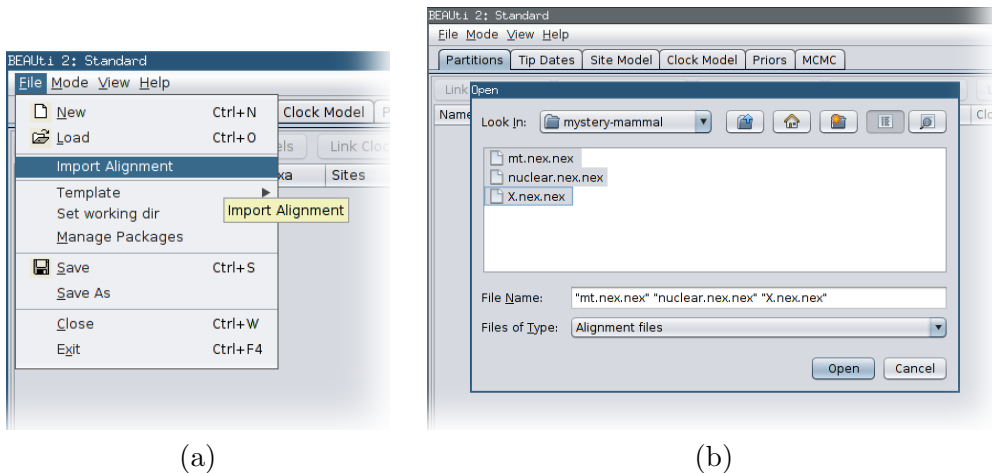

Figure 1: Loading multiple alignments into BEAUti.

1.2 Site model

Open the SITE MODEL pane. Here we choose, for every gene, the evolutionary models specifying how characters evolve at each site (one aligned position). Do not automatically choose the most general models possible (GTR, Gamma + Invariant Sites, Partitioned Codon positions etc.). Please remember that the more general models have more parameters, and this may result in longer runs and slower mixing. This is the time to display your superior knowledge of the data! Sometimes performing an exploratory run(s) on a single loci can help, especially when the simpler model is a special case of a general one. Sometimes the simpler model is represented by particular parameter values, and checking if the credible interval(s) contain those specific values can be a factor in the decision.

In this particular case we'll use the HKY substitution model, but will change the 'Frequencies' to Empirical, as shown in the following figure:

Repeat for each loci. Please note that I know absolutely nothing about this particular data, and it is entirely possible using the GTR or partitioning is the better choice.

1.3 Clock model

Now move to the CLOCK MODEL pane. Here you choose the molecular clock model for each gene. The same considerations as in the site model apply: stay with the strict clock unless you know otherwise.

You may have noticed that exactly two of the three genes are marked as 'Estimate'. In general we can't infer the absolute rate from contemporaneous data (all samples collected at the same time), but we can infer relative rates. The unmarked loci is the reference rate, which is by default set to one. Other rates will be relative to the reference: a rate of 2 (with the reference being 1) means 'evolving twice as fast as the reference'.

In general it is best to pick the most stable reference. Here this would be the mtDNA, since it evolves faster, and so the sequences in that loci will be more divergent and contain more information. Ensure that the rate of 'mt.nex' is unchecked and the other two are checked. To do this, you'll first need to open the 'Mode' menu and deselect 'Automatic set clock rate', as shown below:

Then, select each of the loci names in turn from the list on the left hand side of the screen, making sure that 'estimate' is checked for X and nuclear but unchecked for mt, as shown in figures below:

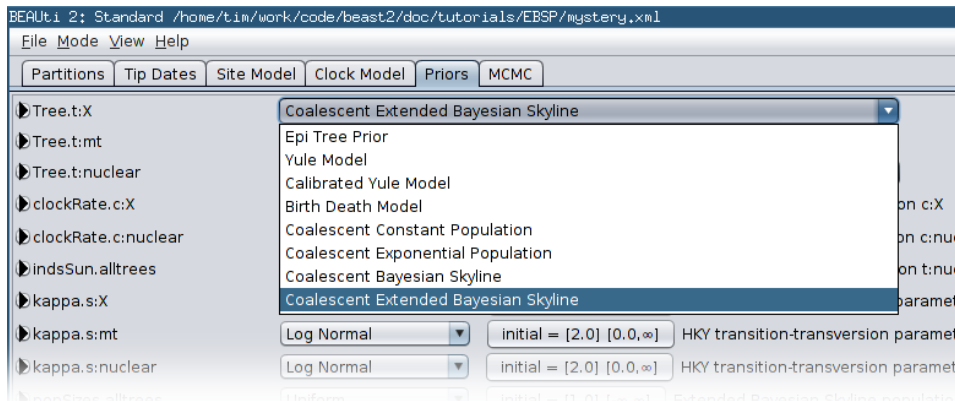

The units of the time axis for the trees and population size is the same as the reference rate. When it equals 1, time is measured in substitutions. When we have an estimate of the reference, it may be more convenient to plug it in and have time in years. Since this is a mammal, I will arbitrarily pick a rate of 0.05 per million years. Double-Click on the 1.0 rate for the mt locus and enter 0.05 and times from the analysis will be in millions of years.

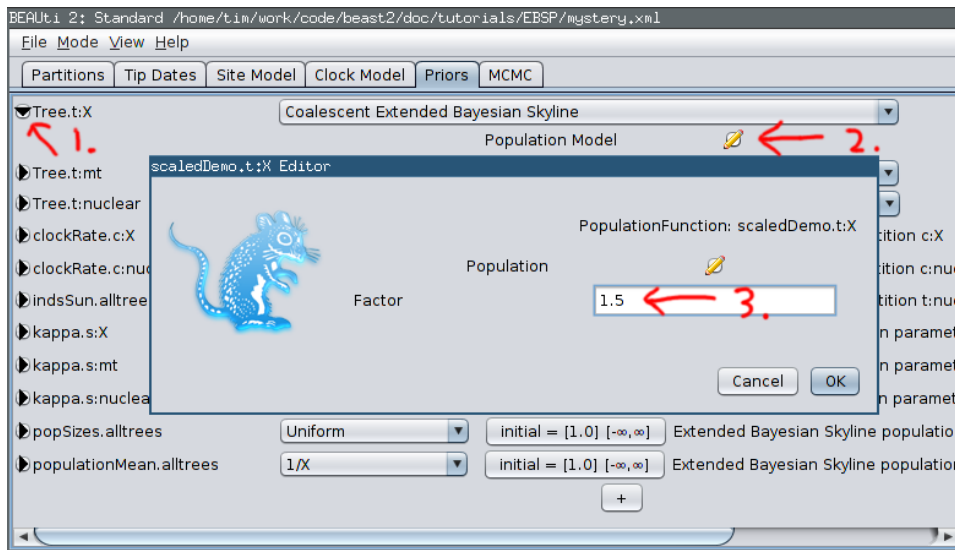

To make a smoother start you should change the other starting rates say to 0.005. Note that we set the reference rate to a known fixed value, but that can be relaxed too. It is possible to let the rate vary (by checking it's 'Estimate' box as well), and place a prior on the rate parameter in the priors section (which is clockRate.c:mt in this specific case). You have to realize that the rate will not be estimated—there is no data here to make that possible—it will simply follow the prior. But the uncertainty regarding the exact value will be reflected in all other estimates.

1.4 Priors

Now, switch to the PRIORS pane. The first thing we need to do here is set the prior for each of the gene trees to 'Coalescent Extended Bayesian Skyline'. Do this by selecting this option from the drop-down menu to the right of 'Tree.t:X', 'Tree.t:mt' and 'Tree.t:nuclear', as shown below:

Once this is complete, click the arrow to the left of Tree.t:X, then click the pencil icon to the right of the 'PopulationModel' text that appears. As shown in the following figure, this will bring up a dialog containing a text field that allows you to edit the scale factor for the population size applied to this particular gene tree:

This allows us to account for the ploidy of each locus. Since this gene is on the X chromosome, we apply a scale factor of 1.5 as each member of the population has 1.5 copies of this gene on average.

Perform these same steps to set the scale factors for the mtDNA and nuclear genes to 0.5 and 2 respectively. (We use 0.5 for mtDNA because only the female mtDNA contributes to the effective population size.)

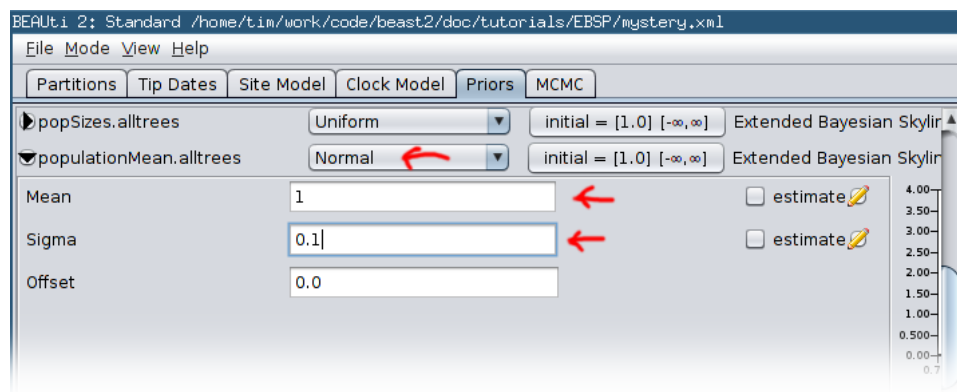

Next, we replace the improper uniform priors on the two estimated clock rates with proper uniform priors by setting a finite upper bound of 1.0 for each. Do this by clicking the arrows to the left of clockRate.c:X and clockRate.c:nuclear and replacing 'infinity' with 1.0, as shown in the following figure:

This should be well above any likely value for the clock rates, but improves mixing by preventing the inference algorithm from exploring implausible

values.

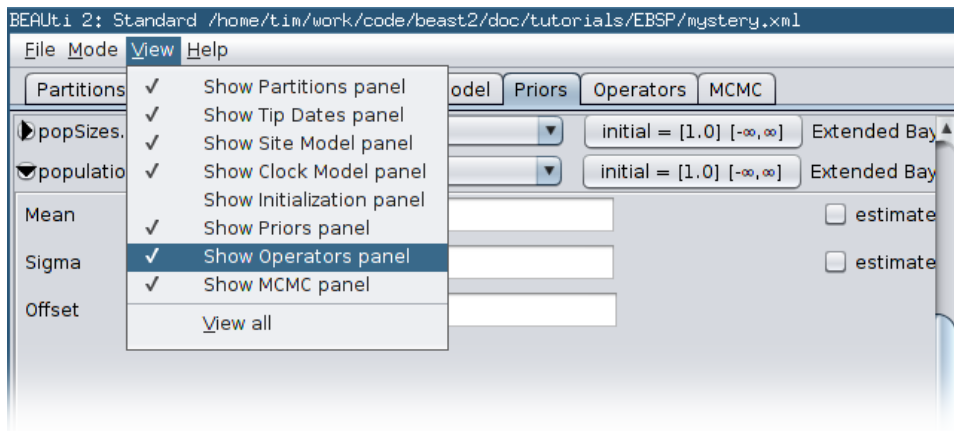

Finally, we modify the hyper-prior on the mean of the population size distribution. By default this is an improper $1/x$ prior which is in general a sensible option. Unfortunately though, this can lead to poor mixing and necessitate runs much longer than we have time for in a tutorial such as this. Thus, to improve the rate of convergence, we replace this with a tight Gaussian prior centred on 1.0 with a standard deviation of 0.1. Set this by selecting ‘Normal’ from the drop-down menu next to populationMean.alltrees and adjusting the parameter values as shown in the following figure:

1.5 Operator weights

The MCMC algorithm used by BEAST explores the state space defined by the set of objects (including the parameters and trees) to be inferred by applying stochastic functions called ‘operators’ to modify these objects. How frequently each operator is used is defined by its ‘weight’. While almost any combination of (non-zero) weights will produce the same result in the end, the efficiency with which the algorithm produces effectively independent samples from the posterior can be dramatically influenced by specific choices.

To view the list of operators BEAST will use for this analysis and their weights, select ‘Show operators panel’ from the View menu:

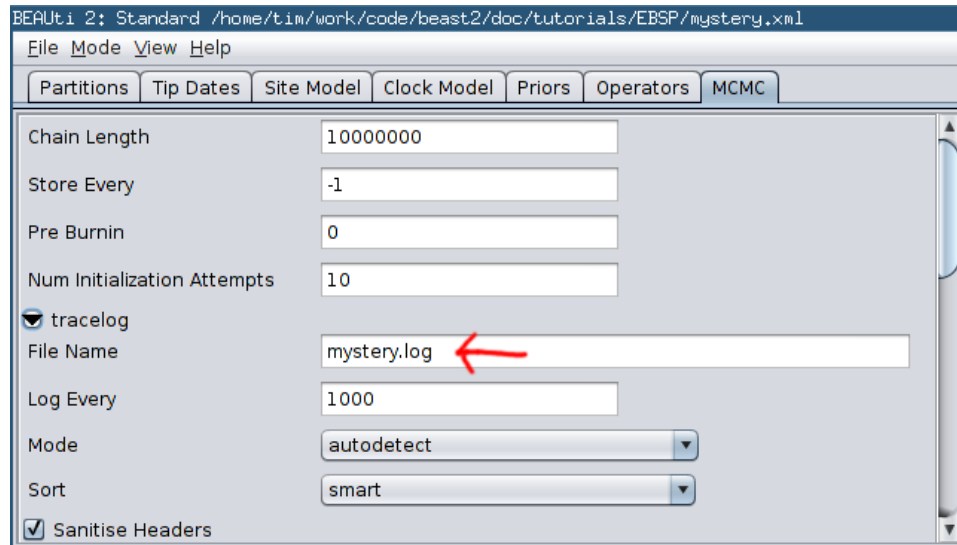

The first change we make is to increase the weights of the operators affecting the κ parameter from the HKY substitution models from 0.1 to 3, as shown by the three red arrows at the top of the following figure:

Secondly, looking at the operators that modify each tree we see that the sum of their weights is about 70. The sum of the default weights for the operators affecting the population function is roughly the same at 60. Given that there are 3 gene trees, modifications to the trees will be proposed about 3 times more frequently than modifications to the population function. We therefore increase the existing population function operator weights by a factor of 3 to even this out a bit. To do this, modify the weights shown by the bottom three red arrows in the previous figure.

1.6 MCMC settings

Finally, open the MCMC pane. Click the arrow to the left of ‘tracelog’ and change the output file name to ‘mystery.log’, as shown in the figure below. Similarly, click the arrow to the left of ‘EBSPLogger’ and change the EBSP output file name to ‘ebsp.log’.

For this tutorial we will retain the default chain length of 10^7 steps, but you should note that this is almost certainly too short for a real analysis.

Once the output file names are set, create a new directory in the tutorial folder named ‘mystery-run’ using whatever method is appropriate under your operating system. Then open the BEAUti File menu and select Save, to save the BEAST XML file representing the analysis in this new directory, using the file name ‘mystery.xml’.

2 Running, Inspecting and Plotting

Run the chain using BEAST. This takes around 5 minutes on a computer with an Intel i5 processor, but your mileage may vary. This will generate a number of output files that are analyzed in the following sections.

2.1 Tracer inspection

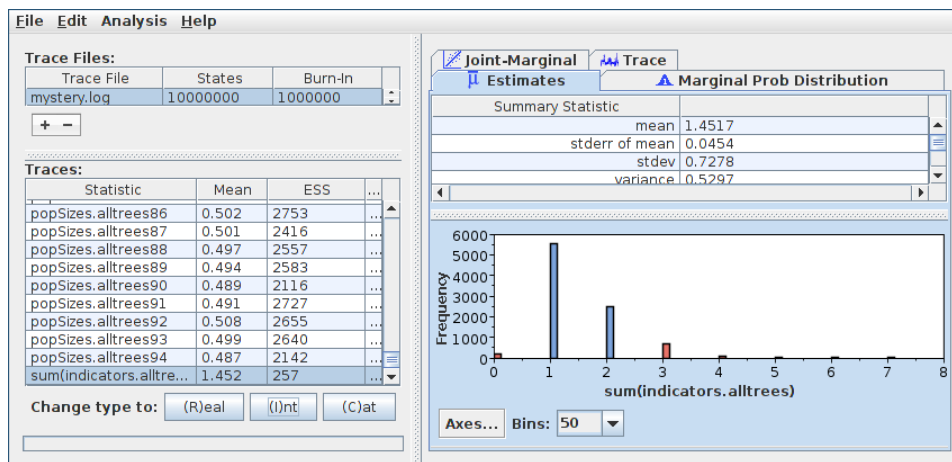

Start up Tracer and load the ‘mystery.log’ file generated by the analysis. I suggest you browse a little on your own before reading further.

You probably looked at the posterior ESS (Effective Sample Size) first. Selecting this and viewing its trace should reveal something similar to what is shown below:

The calculated value is 102, but from a visual inspection of the trace it looks as though the true number of effectively independent samples may be even lower. This is fine, as we knew a chain of 10 million would be too short.

The next step for an EBSP analysis is to look at the number of population changes. To do this, scroll to the very bottom of the table on the left-hand side of the screen and select ‘sum(indicators.alltrees)’. You should see something similar to the following:

This indicates that we can confidently reject a constant population since the 95% HPD excludes 0.

Lastly, you should see that the nuclear and X clock rates come out to approximately 8×10^{-3} and 2×10^{-3} , respectively, which seem reasonable. The kappa values look fine, although there value for X has a very wide credible interval indicating perhaps that there were too few substitutions to enable a good estimate.

2.2 Plotting

The EBSP analysis generated a log file named 'ebsp.log'. (Remember that we set this filename in a previous step.) This can be used in conjunction with the EBSPAnalyzer tool to produce a file that can be loaded into R or some other plotting package for visualizing the demographic history posterior.

In this tutorial however, we will use an R script to produce the visualizations directly. To do this, launch R from the 'mystery-run' folder containing the BEAST output files. (If you are using RStudio or some other graphical front-end to R, you'll probably find a menu option to set the current working directory.) Then execute the following from the R command line:

```
>source("../scripts/plotEBSP.R")
>plotEBSP("ebsp.log", useHPD=FALSE, log="y")
```

The first line loads the functions defined in the R script (which is located in the 'scripts' directory in the tutorial folder). The second produces a visual representation of the EBSP posterior samples contained in the file 'ebsp.log'. The 'useHPD=FALSE' option causes plotEBSP to display 95%

Central Posterior Density (CPD) intervals instead of HPD intervals, while the ‘log=”y”’ option causes the y axis to be displayed using a log scale. A figure similar to the following will be produced:

The function accepts all of the standard R plot options allowing us to, for instance, alter the bounds of the plot or change the axis labels or add a title and thus is quite capable of producing publication-quality output. For instance, to generate a close-up with a linear vertical scale we can use

```
>plotEBSP("ebsp.log", useHPD=FALSE, xlim=c(0, 0.03))
```

which produces

This displays a ten-fold increase over the past 20000 years (remember our times are in Myears). If we assume a generation time of 1 year we get a

current effective population size of around 1 million¹. This is a very large number, but remember this is for illustration purposes only. The actual numbers depend on choice of mutation rate and generation time. Ignoring this objection, let us explore the result a little more.

First note the wide credible intervals. Three genes will rarely give tight bounds when dealing with population sizes. The need for more genes when estimating effective population size can not be overemphasized. Especially when considering that I used only 32 sequences out of a about 128. For the purpose of this analysis the effort in sequencing this large number is wasted: sequencing more genes, if possible, would greatly improve the results.

Secondly, recall that the EBSP prior allows the population (or rather its slope in the case of the linear variety) to change only at points which correspond to events on one of the gene trees. Because these points are generated by something akin to a coalescent process, they are not at all evenly distributed through time. To get an idea of their distribution, we can use another function which is provided by the plotEBSP.R script:

```
>plotEBSPTimesHist("ebsp.log")
```

which produces the following figure:

The spike in the histogram at time 0 is caused by the populations always having a “change” point at this time.

¹If generation time was 10 years, 1M years would be 10^5 generations and so an N_e of 1 would be 10^5 individuals

Note the horizontal axis extends only to 0.12, in contrast with the original skyline figure where it extended to over 0.4. The histogram is constructed to include 95% of the tree event times. This figure therefore implies that there are almost no events informing the population dynamics beyond a time of 0.1. Thus, the apparently constant population size beyond this time is due almost exclusively to the prior rather than the data. One possible explanation is that those mammals experienced a bottleneck at this point, perhaps severe enough so that no amount of genes will let us see beyond it.

Finally, lets consider the first skyline figure. The grey area represents an interval which includes 95% of all population histories in the sampled posterior. It can be useful to look more closely at this distribution, as this approach to summarizing the posterior can sometimes be misleading. The following command replaces the uniform grey shading with faint renderings of individual population trajectories:

```
>plotEBSP("ebsp.log", useHPD=FALSE, plotPopFunctions=TRUE, log="y")
```

Note that the transparency of the population function lines can be adjusted using the 'popFunctionAlpha' parameter.

This produces the following figure, which is a full view of the posterior – all of the samples that are summarized by the median and credible interval lines.

In this case, the figure confirms that the 95% confidence intervals are a good representation of the actual sampled population function distribution.
